Remarques:

SYNTHETIC SPEECH
BT PATENT CASE A24529 (PRTY)

This invention relates to synthetic speech and more particularly to a method of synthesising a digital waveform from signals representing phonemes.

There are many circumstances, eg. in telephone systems, where it is convenient to use synthesised speech. In some applications the starting point is an electronic representation of conventional typography, eg. a disk produced by a word processor. Many stages of processing are needed to produce synthesised speech from such a starting point but, as a preliminary part of the processing, it is usual to convert the conventional text into a phonetic text. In this specification the signals representing such a phonetic text will be called "phonemes". Thus this invention addresses the problem of converting the signals representing phonemes into a digital waveform. It will be appreciated that the digital waveforms are common place in audio technology and digital-to-analogue converters and loud speakers are well known devices which enable digital waveforms to be converted into acoustic waveforms.

Many processes for converting phonemes into digital waveforms have been proposed and it is conventional to do this by means of a linked database comprising a large number of entries, each having an access portion defined in phonemes and an output portion containing the digital waveform corresponding to the access phonemes. Clearly all the phonemes should be represented in the access portions but it is also known to incorporate strings of phonemes in addition. However, existing systems only take into account the phoneme strings contained in the access portions and do not further take into account the context of the strings.

This invention, which is defined in the claims, uses a linked database to convert strings of phonemes into digital waveform but it also takes into account the context of the selected phoneme strings. The invention also comprises a

novel form of database which facilitates the taking into account of the context and the invention also includes the method whereby the preferred database strings are selected from alternatives stored therein.

5   A preferred embodiment of the invention will now be described by way of example.

GENERAL DESCRIPTION

          This general description is intended to identify some of the important integers of a preferred embodiment of the

10 invention.   Each of these integers will be described in greater detail after this general description.

          The method of the invention converts input signals representing a text expressed in phonemes into a digital waveform which is ultimately converted into an acoustic wave.

15 Before its conversion, the initial digital waveform may be further processed in accordance with methods which will be familiar to persons skilled in the art.

          The phoneme set used in the preferred embodiment conform to the SAMP-PA (Speech Assessment Methologies -

20 Phonetic Alphabet) simple set number 6.   It is to be understood that the method of the invention is carried out in electronic equipment and the phonemes are provided in the form of signals so that the method corresponds to the converting of an input waveform into an output waveform.

25   The preferred embodiment of the invention converts waveform representing strings of one, two or three phonemes into digital waveform but it always operates on strings of five phonemes so that at least one preceding and at least one following phoneme is taken into account. This has the effect

30 that, when alternative strings of five phonemes are available, the "best" context is selected.

          It has just been explained that this invention makes particular use of a string of five phonemes and this string will hereinafter be called a "context window" and the five

35 phonemes which constitute the "context window" will be identified as P1, P2, P3, P4 and P5 in sequence.

It is a key feature of this invention that a "data context window" being five consecutive phonemes from the input signal is matched with an "access context window" being a sequence of five consecutive phonemes contained in the database.

5   The prior art includes techniques in which variable length strings are converted into digital waveform. However, the context of the selected strings is not taken into account. Each phoneme comprised in a selected string is, of course, in context with all the other phonemes of the string

10 but the context of the string as a whole is not taken into account. This invention not only takes into account the contexts within the selected string but it also selects a best matching string from the strings available in the database. This specification will now describe important

15 integers of preferred embodiment namely: -

(i)   the definition of "best" as used in the selections;

(ii)   the configuration of the database which stores the signal representations of the data context

20   windows together with their corresponding digital wave forms;

(iii)   the method of selection for (ii) using (i); and

(iv)   picking one of the various alternatives

25   provided by (iii).

DEFINITION OF "BEST"

This invention selects from alternative context windows on the basis of a "best" match between the input context window and the various stored context windows. Since

30 there are many, e.g. 10^8 or 10^{10} possible contexts windows (of 5 phonemes each) it is not possible to store all of them, i.e. the database will lack some of the possible context windows. If all possible context windows were stored it would not be necessary to define a "best" match since an

35 exact correspondence would always be available. However, each individual phoneme should be included in the database

and it is always possible to achieve an exact match for at least one phoneme, in the preferred embodiment it is always possible to match exactly P3 of the data context window with P3 of the stored context window but, in general, further exact matches may not be possible.

5 This invention defines a correlation parameter between two phonemes as follows. Corresponding to each phoneme there is a type-vector which consists of an ordered list of co-efficients. Each of these co-efficients represents a feature of its phoneme, e.g. whether its phoneme is voiced or unvoiced or whether or not its phoneme is a silibant, a plosive or a labil. It is also desirable to include locational features, eg whether or not the phoneme is in a stressed or unstressed syllable. Thus the type vector uniquely characterises its phoneme and two phonemes can be compared by comparing their type-vectors co-efficient by co-efficient; e.g. by using an exclusive-or gate (which is sometimes called an equivalence gate). The number of matchings is one way of defining the correlation parameter. If desired this can be converted to a percentage by dividing by the maximum possible value of the parameter and multiplying by 100.

(As an alternative, a mis-match parameter can be defined e.g. by counting the number of discrepancies in the two type vectors. It will be appreciated that selecting an "best" match is equivalent to selecting a lowest mis-match.)

The primary definition relates to the correlation parameter of a pair of phonemes. The correlation parameter of a string is obtained by summing or averaging the parameters of the corresponding pairs in the two strings. Weighted averages can be utilised where appropriate.

DATABASE

In the preferred embodiment, the database is based on an extended passage of the selected language, eg English (although the information content of the passage is not important). A suitable passage lasts about two or three

minutes and it contains about 1000-1500 phonemes. The precise nature of the extended passage is not particularly important although it must contain every phoneme and it should contain every phoneme in a variety of contexts.

5   The extended passage can be stored in two different formats. First the extended passage can be expressed in phonemes to provide the access section of a linked database. More specifically, the phonemes representing the extended passage are divided into context windows each of which

10   contains 5 phonemes. The method of the invention comprises obtaining best matches for the data context windows with the stored context windows just identified.

The extended passage can also be provided in the form of a digitised wave form. As would be expected, this is

15   achieved by having a reader or reciter speak the extended passage into a microphone so as to make a digital recording using well established technology. Any point in the digital recording can be defined by a parameter, e.g. by the time from the start. Analysing the recording establishes values

20   for the time-parameter corresponding to the break between each pair of phonemes in the equivalent text. This arrangement permits phoneme-to-waveform conversion for any included string by establishing the starting value of the time-parameter corresponding to the first phoneme of the

25   string and the finishing value for the time-parameter corresponding to the last phoneme of the string and retrieving the equivalent portion of database, ie the specified digital waveform. Specifically a conversion for any string of one, two or three phonemes can be achieved.

30   The important requirement is to select the best portion of the extended text for the conversion.

It has already been mentioned that the phoneme version of the extended text is stored in the form of context windows each of five phonemes. This is most suitably achieved by

35   storing the phonemes in a tree which has three hierarchical levels.

The first level of the hierarchy is defined by phoneme

P3 of each window. The effect is that every phoneme gives direct access to a subset of the context windows ie. the totality of context windows is divided into subsets and each subset has the same value of P3.

5   The next level of the tree is defined by phonemes P2 and P4 and, since this selection is made from the subsets defined above, the effect is that the totality of context windows is further divided into smaller subsets each of which is defined by having phonemes ·P2, P3 and P4 in common.

10 (There are approximately half a million subsets but most of them will be empty because the relevant sequence P2, P3, P4 does not occur in the extended text). Empty subsets are not recorded at all so that the database remains of manageable size. Nevertheless it is true that for each triple sequence

15 P2, P3, P4 which occurs in the extended text there will be a subset recorded in the second level of the database under P2, P4 which level will also have been indexed at the first level under P3.

       Finally the second level gives access to a third level

20 which contains subsets having P2, P3 and P4 as exact matches and it contains all the values of P1 and P5 corresponding to these triples. Best matches for data P1 and P5 are selected. This selection completely identifies one of the context windows contained in the extended text and it provides access

25 to time-parameters of said window. Specifically it provides start and finish time-parameters for up to four different strings as follows:-

        (a)   P3 by itself;
        (b)   the pair of phonemes P2 + P3;
30   (c)   the pair of phonemes P3 + P4; and
        (d)   the triple consisting of the phonemes P2 + P3
                 + P4.

       In the first instance, the database provides beginning and ending values of the time-parameter corresponding to each

35 one of the selected strings (a) - (d). As explained above, the time-parameter defines the relevant portion of a digital wave form so that the equivalent wave form is selected.

It should be noted that item (d) will be offered if it is contained in the database; in this case items (a), (b), and (c) are all embedded in the selected (d) and they are, therefore, available as alternatives. If item (d) is not

5 contained in the database then, clearly, this option cannot be offered.

Even if item (d) is missing from the database, then items (b) and/or (c) may still be present in the database. When both of these options are offered they will usually

10 arise from different parts of the database because item (d) is missing. Therefore, depending on the content of the database, the selection will offer (b) alone, or (c) alone, or both (b) and (c). Thus the selection may provide a choice and in any case item (a) is available because it is embedded

15 in the pair.

Finally, even if (b), (c) and (d) are all absent from the database, item (a) will always be present and thus "best match" will be offered for the single phoneme and this will be the only possibility which is offered.

20 It will be apparent that items (b), (c) and (d) imply that strings will overlap. Thus whenever item (c) is selected for any phoneme then item (b) must be available for the next phoneme. If nothing better offered, then the same part of the database will meet the requirements of (c) for

25 the earlier phoneme and (b) for the later but because different correlations are involved better choices may be selected. It will also be apparent that whenever item (d) is available item (c) will be available for the previous phoneme and, in addition, item (b) will be available for the

30 following phoneme. In other words, some of the strings will overlap, ie there will be alternatives for some phonemes such that the same phoneme occurs in different places in different strings. This aspect of the invention is described in greater detail below.

35 It has been emphasised that the preferred embodiment is based on a context window which is five phonemes long. However the full string of five phonemes is never selected.

Even if, fortuitously, the input text contains a string of
five found in the database only the triple string P2, P3, P4
will be used. This emphasises that the important feature of
the invention is the selection of a string from a context

5 and, therefore, the invention selects the "best" context
window of five phonemes and only uses a portion thereof in
order to ensure that all selected strings are based upon a
context.

SELECTION OF "BEST" WINDOW

10   The analysis of the text into phonemes contained in
the database is carried out phoneme by phoneme, but each
phoneme is utilised in its context window. The next part of
the description will be based upon the selection procedure
for one of the data phonemes it being understood that the

15 same procedure is used for each of the data phonemes.

The selected data phoneme is not utilised in isolation
but as part of its context window.   More precisely the
selected data phoneme becomes phoneme P3 of a data window
with its two predecessors and two successors being selected

20 to provide the five phonemes of the relevant context window.
The database described above is searched for this context
window; since it is unlikely that the exact window will be
located, the search is for the best fitting of the stored
context windows.

25   The first step of the search involves accessing the
tree described above using phoneme P3 as the indexing
element. As explained above this gives immediate access to
a subset of the stored context windows. More specifically,
accessing level one by phoneme P3 gives access to a list of

30 phoneme pairs which correspond to possible values of P2 and
P4 of the data context-window.   The best pair is selected
according to the following four criteria.

First criterion Fortuitously , it may happen that one
pair in the sub-set gives an exact match for data P2 and P4.

35 When this happens that pair is selected and the search
immediately proceeds to level 3.   This outcome is unlikely

because, as explained in greater detail above, the string P2, P3, P4 may not be contained in the extended passage.

Second criterion. In the absence of a triple match a left pair will be selected if it occurs. The left-hand match is selected when an exact match for P2 is found and, if alternatives offer, the P4 which has the highest correlation parameter will be selected to give access to level 3 of the tree.

The third criterion is similar to the second except that it is a right-hand pair depending upon an exact match being discovered for P4. In this case access to level 3 is given by the P2 value which provides the highest correlation parameter.

Criterion four occurs when there is no match for either P2 or P3 in which the case the pair P2, P4 with the highest average correlation parameter is selected as the basis of access to level 3.

It will be noted that if criterion 1 succeeds, then it will be possible to take as alternatives a left-hand pair, a right-hand pair and a single value in accordance with criterion 2, 3 and 4.

Even if criterion 1 fails, it is still possible that a left-hand pair will be found by criterion 2 and it is even possible that, simultaneously, a right-hand pair will be found by criterion 3. However because criterion 1 has failed they will be selected from different parts of the database and they will give access to different parts of the tree at level 3.

Finally criterion 4 will only be accepted when criterion 1, 2 and 3 have all failed and it follows that the phoneme P3 cannot be found in triples or pairings when used in other context windows.

Thus, when criterion 1 or 4 are utilised there will only be access to one portion of the tree at the third level but it is possible, when criterion 2 and 3 are used that there will be access to two different parts of the third level.

We have now described how the selection of a context window gives rise to either one or two areas of the third level of the tree. In each case the third level may contain several pairings for phonemes 1 and 5 of the data context

5 window. The pair with the best average correlation parameter is selected as the context window in the access portion of the database. As explained above this context window is converted to digital wave form using the time-parameter.

To re-emphasise; where criterion 1 is used only one

10 context window is selected but is gives (a) rise to four possibilities namely time-parameter ranges for the triple P2 + P3 + P4; (b) for the left-hand pair P2 + P3; for the right-hand pair P3 + P4 and, (a) for the single P3 by itself.

When criterion 2 operates, this provides time-

15 parameter ranges only for the left-hand pair P2 + P3 and for a single P3 by itself. When criterion 3 operates similar considerations apply but the parameter ranges are for the right-hand pair P2 + P3 and for the single P4. If both criterion operate this offers two choices for the single P3

20 and only the one with the higher correlation parameter for P1 + P5 is selected.

Finally when criterion 4 operates there only one possibility namely the phoneme P3 by itself.

The description given above explains how conversions

25 are provided for each phoneme of an input text. Sometimes the method provides a conversion for only a single phoneme and, in this case, no alternatives are offered. In some cases the method provides conversion for strings of two or three adjacent phonemes and, in these circumstances, the

30 conversion provides alternatives for at least one phoneme. In order to complete the selection, it is necessary to reduce the number of alternatives to one. The preferred method of achieving this reduction will now be explained.

The preferred method of making the reduction is

35 carried out by processing a short segment of input text, eg. a segment which begins and ends with a silence. Provided it is not too long a sentence constitutes a suitable segment.

If a sentence is very long, e.g. more than thirty words, it usually contains one or more embedded silences, eg between clauses or other sub-units. In the case of long sentences such sub-units are suitable for use as the segments.

5   The processing of a segment to reduce each set of alternatives to one will now be described. As mentioned, no alternative will be offered for some of the phonemes and, therefore, no selection is required for these phonemes. Alternatives will be available for the other phonemes and the

10 selection is made so as to produce a "best" result for the segment as a whole. This may involve making a locally "less good" selection at one point in the segment in order to obtain "better" selection elsewhere in the segment. The criteria of "better" include: -

15   (i)   taking longer strings rather than shorter strings, and

          (ii)   selecting from strings which overlap rather than from strings which merely abut.

       The rejection of unwanted alternatives produces a

20 position in which each phoneme has one, and only one, conversion. In other words the input text will have been divided into sub-strings of 1, 2 or 3 phonemes matching the database and the beginning and ending values for the selected streams will therefore be established. The output portion

25 of the database takes the form of a digitised waveform and the parameters which have been established define segments of this waveform. Therefore the designated segments are selected and abutted to produce the digital waveform corresponding to the input text. This completes the

30 requirement of the invention.

       Having obtained a digital waveform this can be provided as audible output using conventional digital to analogue conversion techniques and conventional loudspeakers. If desired, the primary digital waveform can be enhanced

35 using techniques known to those skilled in the art.

CLAIMS

1.   A method of converting an input signal into an output
signal, wherein said input signal represents a text in
phonemes and said output signal is a digital waveform
5   convertible into an accoustic waveform corresponding to the
input text, wherein said method comprises:-

(a) dividing said input signal into abutting segments
each of which is stored in the access section of a
linked database,

10   (b) for each segment identified in step (a) retrieving
a segment of digital waveform from the output section
of the database, said output segment being that which
is linked to the input segment, and

(c) concatenating the digital segments retrieved in
15   step (b), said segments being kept in the same order
as the equivalent input segments,

whereby the concaterated digital signal is a waveform
corresponding to the input signal, characterised in that the
output section of the database contains an extended digital
20 waveform having a location parameter for identifying any
point therein whereby the establishment of beginning and
ending location parameters defines a portion of said extended
digital waveform, and step (a) comprises establishing
beginning and ending location parameters for segments of the
25 input signal and step (c) comprises utilising the parameters
established in (a) for retrieving a porton of stored digital
waveform.

2.   A method according to claim 1, wherein step (a)
comprises comparing windows of input signal with windows the
30 input section of the database to establish a closest match
for the input signal.

3.   A method according to claim 2, wherein said window has
a length equivalent to 5 phonemes.

4.   A method according to claim 3, in which the input
35 section of the database is organised into three hierarchical
levels; namely

(i)   a   top   level   containing   single   phonemes

corresponding to the central phoneme of a window;

(ii) a second level which contains the equivalents of the second and fourth phonemes of a window; and

(iii) a lowest level which contains the equivalents of the first and fifth phonemes of the window, whereby identification of a portion of the lowest level identifies a stored window of phonemes;

and the matching comprises selecting an exact match for the central phoneme of the input window from the first level of the hierarchy, selecting a best match for phonemes 2 and 4 from the second level of the hierarchy corresponding to the selected portion of the top level of the hierarchy and, finally, selecting from the bottom level of the hierarchy the best match for phonemes 1 and 5 from that portion of the bottom level which corresponds to the selection in the second level of the hierarchy.
